Conditional probability

Sophie Chowgule

Summary

Conditional probability describes how the likelihood of an event changes when new information is introduced. It is a key concept for understanding relationships between events and making better predictions in uncertain scenarios. This guide outlines how to calculate conditional probabilities, apply the multiplication rule, test for independence, and distinguish between independent and disjoint events.

Before reading this guide, it is highly recommended that you read [Guide: Introduction to probability].

Introduction

Conditional probability is a fundamental concept in probability theory. It describes how the likelihood of an event changes when additional information becomes available. In practice, it is used to update probabilities based on the outcome of related events and is widely applied in areas such as data analysis, forecasting, and decision-making.

It also forms the basis for several key results in statistics, including the multiplication rule, the Law of Total Probability, and Bayes' Theorem. This guide covers the definition of conditional probability, methods for calculating it, ways to test for independence, and highlights the distinction between independent and disjoint events.

Conditional probability

In everyday life, the likelihood of an event often changes as new information becomes available. For example, if you're planning to leave the house and notice dark clouds gathering, you might assume it's more likely to rain and decide to bring an umbrella. This shift in expectation can be understood using **conditional probability**.

Conditional probability is the probability of an event occurring given that another event has already occurred. It helps quantify how one event influences the likelihood of another. More formally:

Definition of conditional probability

If A and B are events, then the **conditional probability** of A occurring given that B has occurred, written as $P(A \mid B)$, is defined as:

$$P(A \mid B) = \frac{P(A \cap B)}{P(B)}.$$

where:

- $P(A \cap B)$ is the probability that both A and B occur.
- $P(B)$ is the probability that B occurs, regardless of whether A occurs.

Note

The notation $P(A \mid B)$ is read as **"the probability of A given B"**, where the vertical bar "|" means "given".

Note

The notation $P(A \cap B)$ is read as **"the probability of A and B"**, where "$\cap$" denotes the **intersection**, the set of outcomes where both events occur.

For a more detailed explanation on the set notations used here, see [Guide: Operations on Sets].

Warning

Conditional probability is only defined when $P(B) > 0$, meaning that the event B must have a chance of occurring. Otherwise, it doesn't make sense to ask about the probability of A given B if B has no chance of occurring. This is also reflected in the formula for conditional probability since dividing by zero would make $P(A \mid B)$ undefined.

Example 1

Suppose you roll a fair six-sided die. The possible outcomes are $1, 2, 3, 4, 5$, or 6. You are told that the number is greater than 2, so what is the probability that the number is even?

Knowing that the result is greater than 2, the possible outcomes are now $3, 4, 5$, and 6 and among these outcomes, the even numbers are 4 and 6.

To calculate the conditional probability:

$$P(\text{Even} \mid X > 2) = \frac{P(\text{Even} \cap X > 2)}{P(X > 2)}.$$

First, find the individual probabilities:

- $P(\text{Even and } X > 2)$ is the probability of rolling an even number above 2, meaning either a 4 or a 6, so:

$$P(\text{Even} \cap X > 2) = \frac{2}{6}.$$

- $P(X > 2)$ is the probability that the roll is greater than 2, which includes the outcomes $3, 4, 5$, and 6, so:

$$P(X > 2) = \frac{4}{6}$$

Substituting these into the formula gives:

$$P(\text{Even} \mid X > 2) = \frac{2/6}{4/6} = \frac{2}{4} = \frac{1}{2}$$

So, given that the roll is greater than 2, the probability that it is even is $1/2$.

Example 2

Now suppose you draw a card at random from a standard deck of 52 cards. You are told that it is a face card, that is a Jack, Queen, or King. What is the probability that the card is a King?
Since you know the card is a face card, the possible outcomes are now limited to the four Jacks, four Queens, and four Kings, with one King in each suit.
Using the conditional probability formula:

$$P(\text{King} \mid \text{Face card}) = \frac{P(\text{King} \cap \text{Face card})}{P(\text{Face card})}.$$

First, find the individual probabilities:

- $P(\text{King and Face card})$ is the probability that the card is a King. Since there are 4 Kings in the deck:

$$P(\text{King} \cap \text{Face card}) = \frac{4}{52}.$$

- $P(\text{Face card})$ is the probability that the card is any face card. There are 12 face cards in total, so:

$$P(\text{Face card}) = \frac{12}{52}.$$

Substituting these into the conditional probability formula gives:

$$P(\text{King} \mid \text{Face card}) = \frac{4/52}{12/52} = \frac{4}{12} = \frac{1}{3}.$$

So, given that the card is a face card, the probability that it is a King is $1/3$.

Multiplication rule

Sometimes you want to find the probability that two events both occur. For example, suppose you draw two cards from a deck, one after the other. You might know the probability that the first card is a Queen, and you might also know the probability that the second card is a Queen given that the first card was a Queen. What if you want to find the probability that both cards are Queens?

The **multiplication rule** allows you to calculate the probability that two events both occur, using a conditional probability and the probability of one of the events. It is especially useful when you have partial information about two related events.

Multiplication rule

If A and B are events, then the probability that both occur, $P(A \cap B)$, is given by:

$$P(A \cap B) = P(B)P(A \mid B).$$

where:

- $P(B)$ is the probability that B occurs, regardless of whether A occurs.
- $P(A \mid B)$ is the probability that A occurs given that B has occurred.

Tip

The multiplication rule also works the other way around:

$$P(A \cap B) = P(A)P(B \mid A)$$

Both forms are correct, so choose the one that matches the information you have.

Note

The multiplication rule comes from rearranging the definition of conditional probability:

$$P(A \mid B) = \frac{P(A \cap B)}{P(B)}$$

To get $P(A \cap B)$, multiply both sides by $P(B)$:

$$P(A \mid B)P(B) = \frac{P(A \cap B)}{P(B)}P(B)$$

The $P(B)$ terms cancel out on the right-hand side, which gives the multiplication rule:

$$P(A \cap B) = P(B)P(A \mid B)$$

Example 3

Suppose you draw two cards from a standard deck of cards, one after the other, without replacement. What is the probability that both cards drawn are queens?
To solve this, use the multiplication rule:

$$P(\text{First queen} \cap \text{Second queen}) = P(\text{First queen})P(\text{Second queen} \mid \text{First queen}).$$

First, calculate the probability that the first card is a queen and the probability that the second card is a queen given the first was a queen. There are 4 queens in a deck of 52 cards, so:

$$P(\text{First queen}) = \frac{4}{52}.$$

If the first card was a queen, there are now 3 queens remaining in a 51 card deck:

$$P(\text{Second queen} \mid \text{First queen}) = \frac{3}{51}$$

Substituting these into the multiplication rule gives:

$$P(\text{Two queens}) = (\frac{4}{52})(\frac{3}{51}) = \frac{12}{2652} = \frac{1}{221} \approx 0.00452.$$

So, the probability of drawing two queens without replacement is approximately 0.00452.

Checking for independence using conditional probability

Conditional probability can also be used to check whether two events are **independent**. If two events A and B are independent, then knowing that B has occurred does not change the probability of A occurring. In other words:

$$P(A \mid B) = P(A).$$

This is equivalent to:

$$P(A \cap B) = P(A)P(B)$$

If either of these conditions do not hold, then the probability of A is affected by the occurrence of B, which means A and B are **dependent** events.

Tip

For a more detailed explanation of independent and dependent events, see [Guide: Introduction to Probability].

Example 4

Imagine you roll a fair six-sided die as in example 1. Let A be the event that the die shows an even number, and let B be the event the die shows a number greater than 4.

First, find:

- $P(A)$, the probability the die shows an even number $(2, 4$, or $6)$:

$$P(A) = \frac{3}{6} = \frac{1}{2}.$$

- Now find $P(A \mid B)$, the probability the number is even given that it is greater than 4. The outcomes greater than 4 are 5 and 6 and among the two, only 6 is even. So:

$$P(A \mid B) = \frac{1}{2}$$

Since:

$$P(A \mid B) = \frac{1}{2} = P(A)$$

the events A and B are independent.

Example 5

Suppose you draw a card at random from a standard deck. Let A be the event that the card is a Queen, and let B be the event that the card is a face card, a Jack, Queen, or King.
First, find the individual probabilities:

- $P(A)$ is the probability the card is a Queen. As there are 4 Queens in the deck:

$$P(A) = \frac{4}{52} = \frac{1}{13}.$$

- $P(B)$ is the probability the card is a face card. As there are 12 face cards in total:

$$P(B) = \frac{12}{52} = \frac{3}{13}.$$

- $P(A \cap B)$ is the probability the card is both a Queen and a face card. Since all Queens are face cards, this is equal to the probability of drawing a Queen:

$$P(A \cap B) = \frac{4}{52} = \frac{1}{13}.$$

Now check whether the multiplication rule holds:

$$P(A)P(B) = (\frac{1}{13})(\frac{3}{13}) = \frac{3}{169}$$

But:

$$P(A \cap B) = \frac{1}{13}$$

And since:

$$P(A \cap B) = \frac{1}{13} \neq \frac{3}{169} = P(A)P(B),$$

the events A and B are **dependent**.

Disjoint events

When working with probability, it's important to understand the difference between **disjoint** events and **independent** events. These terms are often confused, but they describe fundamentally different relationships between events.

- **Disjoint** events (also called **mutually exclusive** events) are events that cannot occur at the same time. If A and B are disjoint, then:

$$P(A \cap B) = 0.$$

For example, flipping a coin once cannot result in both heads and tails.

- **Independent** events are events where the outcome of one does not affect the probability of the other. If A and B are independent, then:

$$P(A \cap B) = P(A)P(B).$$

For example, flipping a coin and rolling a die are independent events because the result of the coin flip does not change the probability of the die roll.

Feature	Disjoint Events	Independent Events
Can both events occur at the same time?	No	Yes
Formula	$P(A \cap B) = 0$	$P(A \cap B) = P(A)P(B)$
Relationship between events	If one happens, the other cannot	One happening does not change the probability of the other

Table 1: Table comparing the key differences between disjoint and independent events.

Quick Check Problems

1. Are the following statements true or false?

(a) Conditional probability is only defined when the probability of the given event is greater than zero.

(b) If $P(A \mid B) = P(A)$, then A and B are independent.

(c) Disjoint events are always independent.

2. A card is drawn at random from a standard deck of 52 cards.

(a) Given that the card is red, what is the probability that it is a heart?

(b) Given that the card is a face card, what is the probability that it is a King?

3. A bag contains 3 green sweets and 2 yellow sweets. Two are picked without replacement. What is the probability that both are green?

4. In a study:
$P(A) = 0.4$, $P(B) = 0.5$, and $P(A \cap B) = 0.2$
Are events A and B independent or dependent?

5. For each pair of events, decide whether they are disjoint, independent, both, or neither.

(a) $A =$ "rolling an even number", $B =$ "rolling a number greater than 4" (on a fair six-sided die)

(b) $A =$ "drawing a Queen", $B =$ "drawing a face card" (from a standard deck)
